Abstract

We propose a new method of discovering causal structures, based on the detection of local, spontaneous changes in the underlying data-generating model. We analyze the classes of structures that are equivalent relative to a stream of distributions produced by local changes, and devise algorithms that output graphical representations of these equivalence classes. We present experimental results, using simulated data, and examine the errors associated with detection of changes and recovery of structures.

1 Introduction

In recent years, several graph-based algorithms have been developed for the purpose of inferring causal structures from empirical data. Some are based on detecting patterns of conditional independence relationships [Pearl and Verma, 1991, Spirtes et al., 1993], and some are based on Bayesian approaches [Heckerman et al., 1997, Cooper, 1999]. These discovery methods assume static environment, that is, a time-invariant distribution and a time-invariant data-generating model, while attempting to infer structures that encode dynamic aspects of the environment, for example, how probabilities would change as a result of interventions. This transition, from static to dynamic information, constitutes a major inferential leap, and is severely limited by the inherent indistinguishability (or equivalence) relation that governs Bayesian networks [Verma and Pearl, 1990].

One way of overcoming this basic limitation is to augment the data with partial causal knowledge, if such is available. [Spirtes et al., 1993], for exam-

ple, discussed the use of experimental data to identify causal relationships. [Cooper and Yoo, 1999] discussed a Bayesian method of causal discovery from a mixture of observational and experimental data.

We propose a new method of discovering causal relations in data, based on the detection and interpretation of local spontaneous changes in the environment. While previous methods are based on static statistical features of the data, our proposal aims at exploiting dynamic changes in that data. Such changes are always present in any realistic domain that is embedded in a larger background of dynamically changing conditions. For example, natural disasters, armed conflicts, epidemics, labor disputes, and even mundane decisions by other agents, are unexpected eventualities that are not naturally captured in distribution functions. The occurrence of such eventualities tend to alter the distribution under study and yield changes that are markedly different from ordinary statistical fluctuations. Whereas static analysis views these changes as nuisance, and attempts to adjust and compensate for them, we will view them as a source of information about the data-generating process. A controlled experimental study may be thought of as a special case of these environmental changes, where the external influence involves fixing a designated variable to some predetermined value. In general, however, the external influence may be milder, merely changing the conditional probability of a variable, given its causes. Moreover, in marked contrast to controlled experiments, we may not know in advance the nature of the change, its location, or even whether it took place; these may need to be inferred from the data itself.

The basic idea has its roots in the economic literature. The economist Kevin Hoover (1990) attempted to infer the direction of causal influences among economic variables (e.g., employment and money supply) by observing the changes that sudden modifications in the economy (e.g., tax reform, labor dispute) induced in the statistics of these variables. Hoover assumed that the conditional probability of an effect given its causes

---

*This is part-I of a two-part paper submitted to UAI-01. Part-II is entitled: Causal Discovery from Changes: a Bayesian Approach.
remains invariant to changes in the mechanism that generates the cause, while the conditional probability of a cause given the effect would not remain invariant under such changes. This asymmetry may be useful in distinguishing cause and effect.

Today we understand more precisely the conditions under which such asymmetries would prevail and how to interpret such asymmetries in the context of large, multi-variate systems. Whenever we obtain reliable information (e.g., from historical or institutional knowledge) that an abrupt local change has taken place in a specific mechanism that constrains a given family of variables, we can use the observed changes in the marginal and conditional probabilities surrounding those variables to determine the direction of causal influences in the domain. The statistical features that remain invariant under such changes, as well as the causal assumptions underlying this invariance, are encoded in the causal diagram at hand, and can be used therefore for testing the validity of a given structure. Likewise, conflicts between observed and predicted changes can be used for automatic restructuring of the topology of the structure at hand.

2 Causal Models and Mechanism Change

Let our problem domain be a set of discrete random variables $V = \{V_1, \ldots, V_n\}$. We assume that a causal model over $V$ is a pair $M = \langle G, \Theta_G \rangle$, where $G$ is a DAG over $V$, called a causal diagram, and $\Theta_G$ is a set of probability parameters. We assume that each variable $V_i$ can take values from a finite domain, $\text{Dom}(V_i) = \{v_{i1}, \ldots, v_{ir_i}\}$, where $r_i$ is the number of states of $V_i$. We use $Pa_i$ to represent the set of parents of $V_i$ in a causal diagram $G$ and $\text{Dom}(Pa_i)$ to represent the set of states of $Pa_i$. Let $\theta_{v_i|Pa_i}, v_i \in \text{Dom}(V_i), Pa_i \in \text{Dom}(Pa_i)$ denote the multinomial parameter corresponding to the conditional probability $P(v_i|Pa_i)$. We will use the following notations: $\theta_{v_i|Pa_i} = \{\theta_{v_i|Pa_i} | v_i \in \text{Dom}(V_i)\}$, $\Psi_i = \bigcup_{Pa_i \in \text{Dom}(Pa_i)} \theta_{v_i|Pa_i}$, $\Theta_G = \bigcup_{i=1}^n \Psi_i$. Assuming the Causal Markov condition [Spirtes et al., 1993], a causal model $M = \langle G, \Theta_G \rangle$ generates a probability distribution

$$P(v) = \prod_i \theta_{v_i|Pa_i}.$$  

A probability distribution $P(V)$ is said to be compatible with a causal diagram $G$ if $P(V)$ can be generated by some causal model $M = \langle G, \Theta_G \rangle$.

The factorization in Eq. (1) obtains causal character through the assumption of modularity; each family in the causal diagram represents an autonomous physical mechanism and is subjected to change without influencing other mechanisms. We formally define mechanism change as follows.

**Definition 1 (Mechanism Change)** A mechanism change to a causal model $M = \langle G, \Theta_G \rangle$ at a variable $V_i$ is a transformation of $M$ that produces a new model, $M_{V_i} = \langle G, \Theta'_G \rangle$, where $\Theta'_G = \Psi_i \cup (\Theta_G \setminus \Psi_i)$ and $\Psi_i$ is a set of parameters having different values with the parameters in $\Psi_i$.

We assume in this paper that the parent set $Pa_i$ does not change in a mechanism change. An intervention that fixes $V_i$ to a particular value is a special case of a mechanism change. Let $P(V)$ be the distribution generated by $M$, as in Eq. (1). Then the distribution generated by $M_{V_i}$ is given by

$$P_{V_i}(v) = \theta_{v_i|Pa_i} \prod_{j \neq i} \theta_{v_j|Pa_j},$$

(2)

We will call $(P, P_{V_i})$ a transition pair (TP) and $V_i$ the focal variable of the transition. Assume that a series of mechanism changes occurred successively to a causal model $M = \langle G, \Theta_G \rangle$, and let $F = (V_{i1}, \ldots, V_{ik})$ denote the corresponding sequence of focal variables. We use $P_{TS} = (P^0, P^1, \ldots, P^k)$ to denote the sequence of distributions generated by such a series, and call the pair $(P_{TS}, F)$ a transition sequence (TS).

As oracles for cause-and-effect relations, causal models can predict the effects that any external or spontaneous changes have on the distributions. Conversely, by detecting how probability distributions change under various mechanism changes, we obtain information on the structure of the model generating those distributions. In this paper, we assume that we are given a TS $(P_{TS}, F)$ corresponding to some causal diagram $G$, and our task is to recover $G$. We will then assume that we have a sequence of datasets $\mathcal{D}_{TS} = \{D^0, \ldots, D^k\}$, where each $D^i$ is a set of random samples from a distribution $P^i$, such that each pair $(P^{i-1}, P^i)$ is a TP with focal variable $V_{i}$, and our task will be to recover a causal diagram (or a set of diagrams) that can generate $\mathcal{D}_{TS}$. First, we study what can be learned from a TS.

3 Indistinguishability of Causal Diagrams

The statistical information of any causal diagram is completely encoded in the independence relationships among the variables. Therefore, every distribution compatible with a causal diagram $G_1$ is also compatible with another diagram $G_2$ if and only if $G_1$ and $G_2$ are independence equivalent, i.e., they encode the same dependency/independency information. Two causal diagrams are statistically indistinguishable given one static distribution if and only if they are independence equivalent. The graphical conditions for independence equivalence are given by the following theorem.
**Theorem 1 (Independence Equivalence)** Two causal diagrams are independence equivalent if and only if they have the same skeletons and the same sets of v-structures, that is, two converging arrows whose tails are not connected by an arrow (Verma and Pearl 1990).

Now assume that we have a TP. A causal diagram $G$ is said to be **compatible with a transition pair** $(P, P_{V_i})$ if $P$ can be generated by a causal model $M = \langle G, \Theta_G \rangle$ and $P_{V_i}$ can be generated by a causal model $M_{V_i} = \langle G, \Theta_{G}^{M_{V_i}} \rangle$ resulted from a mechanism change to $M$ at $V_i$. Note that a causal diagram could be compatible with both $P$ and $P_{V_i}$ but not compatible with the TP $(P, P_{V_i})$. Among those independence-equivalent diagrams compatible with both $P$ and $P_{V_i}$, a TP $(P, P_{V_i})$ can distinguish those that can generate $P_{V_i}$ from $P$ with a **single** mechanism change from those that can not. Two causal diagrams $G_1$ and $G_2$ are called **transition pair equivalent** with respect to a TP with focal variable $V_i$, or $V_i$-transition equivalent, if every TP $(P, P_{V_i})$ compatible with $G_1$ is also compatible with $G_2$. Two causal diagrams are statistically indistinguishable given a TP $(P, P_{V_i})$ if and only if they are $V_i$-transition equivalent.

**Theorem 2 (Transition Pair Equivalence)** Two causal diagrams $G_1$ and $G_2$ are $V_i$-transition equivalent if and only if they have the same skeletons, the same sets of v-structures, and the same sets of parents for $V_i$.

**Proof:** Let $G_1$ be compatible with a TP $(P, P_{V_i})$. $G_2$ must have the same skeletons and the same sets of v-structures as $G_1$ to be compatible with $P$ (and $P_{V_i}$) by Theorem 1. We have the following decomposition:

$$P(v) = P(v_i|pa_{i1}^1) \prod_{j \neq i} P(v_j|pa_{j2}^2) = P(v_i|pa_{i2}^2) \prod_{j \neq i} P(v_j|pa_{j2}^2),$$

where $pa_{i1}^1$ and $pa_{i2}^2$ are parents of $V_i$ in $G_1$ and $G_2$ respectively. $G_1$ is compatible with the TP $(P, P_{V_i})$, hence can generate $P_{V_i}$ from $P$ by a mechanism change at $V_i$:

$$P_{V_i}(v) = P_{V_i}(v_i|pa_{i1}^1) \prod_{j \neq i} P(v_j|pa_{j2}^2).$$ (4)

Plugging the expression for $\prod_{j \neq i} P(v_j|pa_{j1}^1)$ from Eq. (3) into Eq. (4), we have

$$P_{V_i}(v) = P_{V_i}(v_i|pa_{i1}^1) \frac{P(v_i|pa_{i2}^2)}{P(v_i|pa_{i1}^1)} \prod_{j \neq i} P(v_j|pa_{j2}^2).$$ (5)

$G_2$ is also compatible with the transition pair $(P, P_{V_i})$ if and only if

$$P_{V_i}(v) = P_{V_i}(v_i|pa_{i2}^2) \prod_{j \neq i} P(v_j|pa_{j2}^2).$$ (6)

Eqs. (5) and (6) lead to

$$P_{V_i}(v_i|pa_{i1}^1) \frac{P(v_i|pa_{i2}^2)}{P(v_i|pa_{i1}^1)} = P_{V_i}(v_i|pa_{i2}^2),$$ (7)

which holds for any distribution $P$ and $P_{V_i}$ if and only if $G_1$ has the same parent set for $V_i$ as $G_2$ ($pa_{i1}^1 = pa_{i2}^2$); if $G_1$ has a different parent set for $V_i$ with $G_2$, Eq. (7) will impose some constraints between $P$ and $P_{V_i}$, and will not hold for arbitrary possible transition pair $(P, P_{V_i})$. \hfill \Box

A TS is simply a series of TP’s. Accordingly, we say that a causal diagram is **compatible with a transition sequence** $P_{TS} = (P^0, P^1, \ldots, P^k) = (V_i, \ldots, V_{i_k})$ if it is compatible with each TP $(P^j, P^{j+1})$ in the sequence. Likewise, two causal diagrams $G_1$ and $G_2$ are called **transition sequence equivalent** with respect to a TS $(P_{TS}, F)$, or $F$-transition equivalent, if every TS $(P_{TS}, F)$ compatible with $G_1$ is also compatible with $G_2$. Two causal diagrams are statistically indistinguishable given a TS $(P_{TS}, F)$ if and only if they are $F$-transition equivalent.

**Theorem 3 (Transition Sequence Equivalence)** Two causal diagrams are $F$-transition equivalent if and only if they have the same skeletons, the same sets of v-structures, and the same sets of parents for variables in $F$.

Theorem 3 says that a TS determines the directions of the edges between the focal variables and their neighbors (among the set of independence-equivalent diagrams). Figure 1 shows an example of TS equivalence.

![Figure 1: TS equivalence. Assuming (a) is the actual causal diagram. (a)-(d) are independence equivalent. (e)-(g) are $B$-transition equivalent. A mechanism change on $A$ determines a unique causal diagram (h).](image)
Our ability to recover causal diagrams is limited by the statistical indistinguishability of causal models with given data. Given a TS, the most we can expect to recover is a set of causal diagrams that are TS-equivalent, as defined by Theorem 3. We may find this equivalence class by detecting independence relations and distribution changes.

4 Learning Causation by Detecting Changes

In this section, we identify the causal information that can be learned by detecting various changes in the probability distributions, in particular, changes in the marginal probability of each variable. The following theorem is obvious.

Theorem 4 A mechanism change at a variable X to a causal model $M = \langle G, \Theta_c \rangle$ may alter the marginal probabilities of the descendants of X in G and can not alter the marginals of non-descendants of X.

It is possible of course that, for some peculiar parameter changes, the marginal probabilities of some descendants of X would not change. When recovering causal information from distributional changes, we impose a restriction on a TS called influentially.

Definition 2 (influentially) A TP $(P, P_X)$ generated by a causal model $\langle G, \Theta_c \rangle$ is said to be influential if for every descendant Y of X in G, the marginal distribution $P_X(Y)$ is different from $P(Y)$. A TS is influential if every TP in the sequence is influential.

Assuming influentially, we can obtain causal information by detecting changes of marginal probabilities.

Given a TP $(P, P_X)$, and assuming that we can test each variable for marginal distribution change, we can draw the following inferences. If the marginal of a variable Y has changed, we conclude that Y is a descendant of X. If the marginal of a variable Z has not changed, we conclude that Z is a non-descendant of X. We thus conclude that $Z < X < Y$ should be a causal order consistent with the causal diagram. Next we discuss how to piece together ordering information of this kind, as obtained from a TS.

4.1 Partitioning the variables

Given a TS $P_{TS}$, $F = (V_1, \ldots, V_k)$, each variable can be characterized by a sequence of 1’s and 0’s, a tag $a_1, \ldots, a_k$, where $a_i$ reflects whether the marginal of that variable changed ($a_i = 1$) or not ($a_i = 0$) in the i-th transition of the sequence. Non-focal variables that are given the same tags cannot be distinguished by the TS (through detecting marginal changes), and no information can therefore be extracted about their relative causal order in the causal diagram. We may put all such variables into a bucket labeled with the same tag, denoted by $B_{a_1 \ldots a_k}$. Clearly, since we have no information on causal relations among variables within the same bucket, all variables in a bucket stand in the same ordering relation to all variables in another bucket. Focal variables need special treatment since they carry more information, and we will put each focal variable into an individual bucket called a focal bucket, denoted by $B_{f_1 \ldots f_k}$.

We classify variables into buckets with the following algorithm.

Algorithm 1 (Partitioning Variable)

Input: a TS $P_{TS}$, $F = (V_1, \ldots, V_k)$.
Output: A set of buckets, each associated with a tag $a_1 \ldots a_k$, and each containing a set of variables.

Put all variables in a bucket B.
For the i-th mechanism change, $i = 1, \ldots, k$

- For each bucket $B_{a_1 \ldots a_{i-1}}$, including focal buckets if it contains the i-th focal variable, put it in a focal bucket $B_{f_1 \ldots f_k}$;
- put other changing variables in $B_{a_1 \ldots a_{i-1}}$;
- put non-changing variables in $B_{a_1 \ldots a_{i-1} 0}$.

We show the partitioning process by an example. Assume that the actual causal diagram is the DAG shown in Figure 2(a) and that we are given a TS $(P, P_X, P_Y)$. In the first transition, with X as the focal variable, $P(Y)$ does not change, hence $B_0 = \{Y\}$; $P(X), P(Z), P(W), P(Q)$ do change, hence we form $B_1 = \{Z, W, Q\}, B_{1f} = \{X\}$. Note that a focal variable is put into an individual bucket. In the second transition, with Y as the focal variable, $P(Y)$ changes, giving $B_{1f} = \{Y\}; P(Z)$ and $P(W)$ change, giving $B_{11} = \{Z, W\}; P(Q)$ and $P(X)$ do not change, giving $B_{10} = \{Q\}$ and $B_{1f} = \{X\}$. As a result, the variables are partitioned into four buckets: $B_{0f} = \{X\}, B_{01} = \{Y\}, B_{10} = \{Q\}, B_{11} = \{Z, W\}$.

4.2 Extracting causal information

We shall now discuss what causal information we can extract from the tags attached to buckets. Consider any two buckets $B_{a_1 \ldots a_k}$ and $B_{b_1 \ldots b_k}$. If there exists a bit such as $a_i < b_i$ (i.e., $a_i = 0$ and $b_i = 1$), it must be that, in the i-th transition, the marginals of variables in $B_{a_1 \ldots a_k}$ did not change and the marginals of variables in $B_{b_1 \ldots b_k}$ did. Therefore, no variable in $B_{a_1 \ldots a_k}$ is a descendant of any variable in $B_{b_1 \ldots b_k}$. On the other hand, if there exists another bit such that $a_j > b_j$ ($a_j = 1, b_j = 0$), then no variable in $B_{b_1 \ldots b_k}$ is a descendant of any variable in $B_{a_1 \ldots a_k}$, which means that there exists no directed path, in particular no edge, between any variable in $B_{a_1 \ldots a_k}$ and any variable in $B_{b_1 \ldots b_k}$. The equality $a_i = b_i, i = 1, \ldots, k$ can
only happen if one of the buckets is a focal bucket, in which case the focal variable is an ancestor of all the variables in the other bucket. In summary, the relation between two buckets \( B_{i1\ldots ik} \) and \( B_{j1\ldots jk} \) is determined as follows:

1. \( a_i \leq b_i, i = 1, \ldots, k \) and \( \exists j, a_j < b_j \): variables in \( B_{i1\ldots ik} \) are non-descendants of variables in \( B_{j1\ldots jk} \), denoted by \( B_{i1\ldots ik} < B_{j1\ldots jk} \).

2. \( a_i \geq b_i, i = 1, \ldots, k \) and \( \exists j, a_j > b_j \): \( B_{i1\ldots ik} > B_{j1\ldots jk} \).

3. There exist two bits \( i \neq j \) such that \( a_i < b_i \) and \( a_j > b_j \): there can be no directed path between any variable in \( B_{i1\ldots ik} \) and any variable in \( B_{j1\ldots jk} \).

4. \( a_i = b_i, i = 1, \ldots, k \): if both buckets are focal buckets then “unknown”, else let the focal bucket be \( B_{i1\ldots ik} \), then \( B_{i1\ldots ik} < B_{j1\ldots jk} \).

Consider the binary relation “\(<\)” on the set of buckets as defined in the Algorithm 2. We have the following theorem.

**Theorem 5** The binary relation “\(<\)” on the set of buckets is a partial order.

**Proof:** The relation is transitive. If \( B_{i1\ldots ik} < B_{j1\ldots jk} \) and \( B_{j1\ldots jk} < B_{c1\ldots ck} \), we have \( a_i \leq b_i \leq c_i, i = 1, \ldots, k \).

1. \( \exists j, a_j < c_j \). If \( B_{c1\ldots ck} \) is not a focal bucket, then we have \( B_{i1\ldots ik} < B_{c1\ldots ck} \). If \( B_{c1\ldots ck} \) is a focal bucket for the \( l \)th transition and \( a_l = 1 \) then \( b_l = 1 \) since \( a_l \leq b_l \leq c_l \), which contradicts \( B_{i1\ldots ik} < B_{c1\ldots ck} \).

2. \( a_i = c_i, i = 1, \ldots, k \). Then \( a_i = b_i = c_i, i = 1, \ldots, k \) and then \( B_{i1\ldots ik} \) has to be a focal bucket and \( B_{j1\ldots jk} \) is not one in order to have the relation \( B_{i1\ldots ik} < B_{j1\ldots jk} \), which then contradicts \( B_{i1\ldots ik} < B_{c1\ldots ck} \).

The relation is antisymmetric. If \( B_{i1\ldots ik} < B_{j1\ldots jk} \) and \( B_{j1\ldots jk} < B_{a1\ldots ak} \), then \( a_i = b_i, i = 1, \ldots, k \). Since they cannot both be focal buckets, they must be the same bucket. \( \square \)

A partially ordered set can be represented by a DAG. We construct a graph with both directed and undirected edges, called an order graph (OG), as follows: a node represents a bucket; for each pair of buckets \( B \) and \( B' \), there is a directed edge \( B \rightarrow B' \) if \( B < B' \); there is an undirected edge \( B \leftarrow B' \) if the relation between them is “unknown”. If we have a perfect statistical test for distributional changes, an OG is a DAG. For the causal diagram shown in Figure 2(a) and the TS \((P, P_X, P_Y)\), the ideal OG is given in Figure 2(b).

In an OG, when \( B \) is a focal bucket, a directed edge \( B \rightarrow B' \) asserts that there exists a directed path from
the focal variable contained in \( B \) to all the variables in \( B' \). Hence, if there is no other mixed directed path, a path that could contain undirected edges but no directed edges in the reverse direction, from \( B \) to \( B' \) in the OG, there must be an edge from \( B \) to at least one variable in \( B' \) in the causal diagram. We mark this type of edges as \( B \rightarrow B' \), to distinguish them from those that only represent potential edges in the causal diagram. This information is useful when the child bucket \( B' \) contains only one variable; we then assert that the edge \( B \rightarrow B' \) must exist in the causal diagram. We will call an OG with marked edges a marked order graph (MOG); an example is shown in Figure 2(c).

An algorithm for constructing a MOG is given in the following.

**Algorithm 3 (Constructing MOG)**

**Input:** an influential TS with known focal variables.

**Output:** a marked order graph.

1. Put variables into buckets using Algorithm 1.
2. Extracting relations among buckets using Algorithm 2.
3. Let each bucket be a node.
4. For each pair of nodes \( B \) and \( B' \)
   - If \( B < B' \), add an edge \( B \rightarrow B' \).
   - If \( B' < B \), add an edge \( B' \rightarrow B \).
   - If the relation is "unknown", add an edge \( B \rightarrow B' \).
5. For each focal bucket \( B_f \) and each of its child \( B \)
   - If there is no other mixed directed path from \( B_f \) to \( B \), mark the edge as \( B_f \rightarrow B \).

In summary, the information conveyed by a MOG is as follows:

1. An unmarked edge \( B \rightarrow B' \): All variables in \( B \) can be ordered before all variables in \( B' \) in the causal diagram, in other words, there are no directed paths from variables in \( B' \) to variables in \( B \). When \( B \) is a focal variable, there exists a directed path from \( B \) to each variable in \( B' \) in the causal diagram.
2. A marked edge \( B \rightarrow B' \): There exists a directed path from \( B \) to each variable in \( B' \). In the case that both \( B \) and \( B' \) contain one single variable, the edge \( B \rightarrow B' \) must exist in the causal diagram.
3. No edge between \( B \) and \( B' \): there is no directed path, in particular no edge, between any variable in \( B \) and any variable in \( B' \) in the causal diagram.

### 4.3 Limitation of detecting marginal changes

Can we fully recover a causal diagram by detecting marginal distribution changes alone? To fully recover a causal diagram, we must construct a MOG in which each bucket contains only one variable and every edge is marked. This may not, in general, be achieved. Considering a causal diagram \( G \) containing a path \( X \rightarrow Z \rightarrow Y \), it is clear that we can never determine if there is an edge \( X \rightarrow Y \) in \( G \), since all marginal changes produced by transitions would be the same after adding that edge. What is the best we can get then by detecting marginal changes?

Given a DAG \( G \), if we remove an edge \( X \rightarrow Y \) whenever there is a directed path from \( X \) to \( Y \), we get the transitive reduction of \( G \). The transitive reduction of a DAG \( G \) is the graph \( G' \) with the fewest edges such that the transitive closure of \( G' \) is equal to the transitive closure of \( G \). The transitive closure of a DAG \( G \) is the graph \( G'' \) such that an edge \( X \rightarrow Y \) is in \( G'' \) if there is a directed path from \( X \) to \( Y \) in \( G \). By detecting marginal changes in TS's, the best we can hope to get is the transitive reduction of the actual causal diagram. Since to mark an edge \( X \rightarrow Y \), \( X \) must be a focal variable, it follows that every node except leaf nodes must be a focal variable in order to mark every edge in the transitive reduction graph. To further make each bucket contain only one variable, every leaf node having the same set of parents as another leaf node must be a focal variable.

In conclusion, by detecting marginal distribution changes, the best we can learn is the transitive reduction of the causal diagram, and we can achieve it by a TS in which every variable has had its mechanism changed.

### 5 Combining Static and Dynamic Information

In Section 4, we discussed how to extract causal information given a TS by detecting distributional changes. In this section, we briefly describe how to combine this information with that from independence tests.

Given data from a static and stable distribution, we can recover (partially directed) causal diagrams by using conditional independence tests. Several such algorithms have been developed, including IC algorithm [Pearl, 2000, section 2.5] (initially introduced in [Pearl and Verma, 1991]) and PC algorithm [Spirtes et al., 1993]. The output of these algorithms is a partially oriented graph representing an independence-equivalence class as defined by Theorem 1.

To recover a causal diagram from a TS, we first extract causal information by detecting distribution changes.
as described in Section 4, then run the IC algorithm using the causal information as prior knowledge.

We may obtain three types of causal information as shown in Section 4: causal order among certain variables, no edges between certain variables, and certain directed edges. The last two types of information (no-edge and determined-edge) can be incorporated directly. Causal order information can be used to restrict the search of candidate conditional sets and thus reduce the complexity of the IC algorithm. Causal order information can also be used to orient more edges: any undirected edge $X-Y$ can be oriented as $X \rightarrow Y$ if $X$ is ahead of $Y$ in the causal order. These methods of incorporating background knowledge have been discussed in [Spirtes et al., 1993, Section 5.4.5].

After incorporating these causal information as background knowledge, the output of the IC Algorithm would be a partially oriented graph representing the TS equivalence class as defined by Theorem 3. This is due to a theorem in [Meek, 1995] which says that the orientation rules in the IC algorithm are complete even with respect to the background knowledge.

6 Experimental Results

We use $\chi^2$ test to detect distribution changes. Let $D^1$ and $D^2$ be two datasets, consisting of $N_1$ and $N_2$ cases respectively. Let $N_{1x}$ and $N_{2x}$ be the number of cases in $D^1$ and $D^2$ respectively in which a variable $X$ takes the value $x$. To test the hypothesis that $X$ has the same distribution in the two datasets, we compute the quantity

$$\chi^2 = N_1N_2 \sum_x \frac{1}{N_{1x} + N_{2x}} (\frac{N_{1x}}{N_1} - \frac{N_{2x}}{N_2})^2,$$

which is asymptotically a $\chi^2$ distribution with $r_x - 1$ degree of freedom, where $r_x$ is the number of states of $X$. Let the significance level be $\alpha$. If $\chi^2 > \chi^2_{\alpha}$ then we decide “change”, else we decide “no-change”.

A mechanism change at a variable $V_i$ is simulated as follows. Consider parameters in $\theta_{pa_i}$. If $\theta_{v_i;pa_i}$, $\leq 0.5$ then let $\theta'_{v_i;pa_i} = \theta_{v_i;pa_i} + \delta$, else let $\theta'_{v_i;pa_i} = \theta_{v_i;pa_i} - \delta$, where $\delta$ is a parameter for adjusting the change magnitude. The rest of the parameters in $\theta_{pa_i}$ are changed in proportional to their original values as: $\theta'_{v_j;pa_i} = \alpha \theta_{v_j;pa_i}$, $j = 2, \ldots, r_i$, where $\alpha = (1 - \theta'_{v_i;pa_i})/(1 - \theta_{v_i;pa_i})$. When we simulate a mechanism change at $V_i$, we change parameters in $\theta_{pa_i}$ as above for each $pa_i \in Dm(Pa_i)$.

In our experiments, we used data generated from a known network, the Alarm Bayesian network1

![Figure 3: Type I and Type II errors of $\chi^2$ statistics.](image)

[Beinlich et al., 1989]. We used equal sample sizes for all datasets in a TS, that is, a sample size $N$ represents that $N$ cases were generated for each dataset $D^i$ in $\mathcal{D}_{TS} = \{D^0, \ldots, D^k\}$.

6.1 Errors in detecting changes

There are two types of errors in detecting changes: (i) mistaking “no-change” for a “change”, known as type I error and denoted NC2C, and (ii) mistaking “change” as “no-change”, known as type II error and denoted C2NC. Let $G$ be the causal diagram used for generating samples. When a mechanism change occurs at a variable $V_i$, if our test statistics is perfect, all $V_i$’s descendants in $G$ should be identified as “change” and $V_i$’s nondescendants as “no-change”. Let $\text{Dec}_i$ be the number of descendants of $V_i$ in $G$ and $\text{NDec}_i$ be the number of nondescendants of $V_i$. Let $c2nc_i$ be the number of descendants of $V_i$ identified as “no-change” by the $\chi^2$ test, and let $nc2ci$ be the number of non-descendants of $V_i$ identified as “change”. $\text{nc2ci}$ and $\text{c2nc}_i$ represent the number of type I and type II mistakes made by the $\chi^2$ statistics. In any one run, we simulate a mechanism change at each node $V_i$, $i = 1, \ldots, n$, relative to the original network, and compute the C2NC error rate as $\sum_i c2nc_i/\sum_i \text{Dec}_i$ and the NC2C error rate as $\sum_i nc2ci/\sum_i \text{NDec}_i$. We computed an average error rate over $5$ runs.

We varied the change magnitude $\delta$, the sample size, and the significance level $\alpha$, and the results are shown in Figure 3. We see that the NC2C (type I) error rate is nearly the same as the $\alpha$ value for different change magnitudes and sample sizes, as expected. The C2NC (type II) error could be large when the $\alpha$ value is small or the change magnitude is small. This suggests that we should consider using a two-tailed $\chi^2$ test [Silverstein et al., 2000] to control the C2NC error, especially when the sample size is not large. In a two-tailed $\chi^2$ test, we use another threshold $\alpha' > \alpha$ such that we decide “no-change” only when $\chi^2 < \chi^2_{\alpha'}$, but we have to decide “unknown” when $\chi^2 > \chi^2_{\alpha'}$. We will not discuss this method in this paper.
6.2 Errors in order graphs

In an OG, an edge $B \rightarrow B'$ represents that all variables in $B$ can be causally ordered before the variables in $B'$. We call this type of information “order claims”. No edge between $B$ and $B'$ represents the absence of directed paths, in particular edges, between variables in $B$ and those in $B'$; this information will be called “no-directed-path (NDP) claims” and “no-edge claims” respectively. An edge $B \rightarrow B'$ only signals mistakes in the statistical tests and will be called “unknown claims”. We performed the following experiments: for certain $\delta$, $\alpha$, sample size, and focal variables, we generate datasets, construct an OG, count the claims, and check against the true network to compute percentage errors for each type of claims.\footnote{Claims are counted between pairs of variables not between pairs of buckets. Numbers vary with the focal variables picked, hence we did 100 runs, each time randomly picking a sequence of $k$ variables as focal variables, and computed average numbers.}

The results are shown in Table 1 for various sample size $N$, number of focal variables $k$, mechanism change magnitude $\delta$, and significance level $\alpha$. From Table 1, we see that the NDP claims have a high percentage of error; however, if those claims are interpreted as representing no-edge only, then the error rates are much lower. As expected, the error rates are lower when $\delta$, the change magnitude, is larger, and a TS with more focal variables produces more no-edge claims.

7 Conclusion

The main advantage of using local changes as clues for recovering causal structures lies in the potential of extracting causal information that is undetected by static methods. This potential is limited by several factors, the most significant are violation of influentiality (in large networks) and the reliance on broad sets of focal variables. We believe that the former problem can be overcome by restricting the order information extracted to close neighborhoods of the focal variables.

Table 1: Errors in order graphs. $k$: the number of focal variables. $m$: the number of buckets. $E_{o}$: percentage error of order claims. $E_{p}$: percentage error of NDP claims. $E_{e}$: percentage error of no-edge claims. $u$: number of unknown claims.
